DIFFUSE IDIOPATHIC SKELETAL HYPEROSTOSIS (DISH) ON A MALE SKELETON FOUND IN ŽEROTICE, MORAVIA (JEVIŠOVICE CULTURE)

ABSTRACT — A new find of diffuse idiopathic skeletal hyperostosis (DISH) is described from Eneolithic period (Jevišovice culture burial) in South Moravia.

KEY WORDS: Skeletal hyperostosis — DISH — Eneolithic — Moravia.

Degenerative diseases of the big joints and of the vertebral column — arthritis and spondylosis, are the most frequent affections of the locomotion system in modern man. In paleopathology the finds affected by arthritis, and especially by spondylosis, are unusually frequent (Hlaváčková, Vyhnanek 1981) and they form a rather varied picture. When Forester detached in 1969 "the ankylosing vertebral hyperostosis" as an independent nosological unit differing from the current spondylosis, soon appeared descriptions of analogous finds also in the archaeological material (in this country by Vyhnanek, Stloukal and Kolář 1970). In the year 1975 Resnick at al. emphasized that Forester’s ankylosing vertebral hyperostosis has sometimes hyperostotic manifestations also in other parts of the skeleton and this disease is called diffuse idiopathic skeletal hyperostosis — DISH.

It should be emphasized that it is not a real nosological unit in the proper sense of the word. It is a synenom — it is a group of changes of hitherto unclear and evidently also heterogeneous etiology, characterized by increased readiness of the connective tissue to get transformed into bone metaphysically. It happens so that the muscle and ligament attachments easily into the bones. In case of inborn disposition the triggering moment can be microtraumatization, a trauma or an inflammation. Large ossifications forming up to overbridging "osteophytes" (or better synostomophytes) appear especially in the spine, forming on the front right side large relief areas. Their formation is typical around the acromion, elbow, knees, at the calcaneum, etc. Affected are most often people in their fifties and sixties and belong to the obese and muscular types. Many of them suffer from diabetes mellitus or gout. In differential diagnosis it is possible to differentiate it from Bekhterev's disease. On the other hand it is sometimes very difficult to differentiate it from not very clear forms of spondylosis.

The basic difference is that in spondylosis there are always lowered degenerated intervertebral discs. Their degeneration is in fact the cause of spondylosis. With DISH the intervertebral discs may be preserved, of normal thickness, although their lowering cannot be excluded.

This paper was presented at the workshop on "New Finds and Novel Opinions in Paleopathology" held in Brno, Anthrop Institute on October 25, 1987.
Changes that can be regarded as typical DISH were observed on a skeleton in the Moravian Museum found in the excavations of an Eneolithic Jeřišovice Culture site in Žerovice by Dr. Kovářík. The skeleton is dated into the third millennium B.C.

It is a well preserved skeleton of a male of 45—50 years, of robust type. The big joints, as far as preserved, show not serious arthrotic changes. Very conspicuous are the hypertrophic changes in the spine, especially in the cervical, and lumbar parts, and especially in the acrobioclavicular joints. Vertebral column: in its cervical part (Fig. 1) there are well perceptible large osteophytes on the front side of vertebral bodies C 3—4, C 4—5 and C 5—6.

At the transition to the thoracic and lumbar part (Fig. 2) there are also massive osteophytes situated typically on the right side of the vertebral bodies. The most conspicuous finds are at the two acromioclavicular joints. On Fig. 3 we can see from cranial view massive hypercrototic changes on both acromia, especially on the left side. On the preserver processes coracoidei on the left there are typical prickly processes at its base (the attachment of the coracoclavicular ligament and the transversal liga-

ment of the scapula). There are matching changes also on the left clavicle (the right clavicle has not been preserved) — Fig. 4.

Viewed from the caudal side there are well visible osifications with an attachment of tissues, both on the sternal and scapular end.

On the rest of the skeleton (on the pelvis, proximal parts of the femora) there are also hypercrototic changes, but of much more conspicuous extension. The interesting thing is that no pathological osifications were found on the heel bones.
CONCLUSION

The above described changes are typical of the DISH, this applies especially to the symmetry of the affection of the acromio-clavicular joints. The relatively small changes on the pelvis and in the heel bones can be explained by the relatively low age of the individual: as a rule clinically fully developed DISH is diagnosed at about 55—60 years. There is no doubt at all that the palaeopathological finds documenting diffuse idiopathic skeletal hyperostosis (DISH) were observed many times also earlier. In most cases, however, they were interpreted as Bechterev’s disease or spondylitis. In view of the fact that DISH has its undisputable clinical importance in the modern medicine, it is necessary to make more accurate the DISH diagnostics also in the palaeanthropological skeletal material.
