PRIMARY AND SECONDARY SCHOOL CHILDREN
OF THE TRI-CITY (GDAŃSK, GDYNIA, SOPOT)
IN THE LIGHT OF WEIGHT/STATURE$^2 \times 100$

ABSTRACT — The report presents data concerning the weight stature ($W/S^2 \times 100$) index of children and young people living in one of the big Polish conurbations. The main purpose of the work was to define the percentile values for $W/S^2 \times 100$ of examined groups. 15729 girls and boys from 8 to 19 years of age were examined in 1985 and 1986. As the result the following information was obtained:

1. The relationship between $W/S^2$ and age is statistically significant in boys as well as in girls.
2. By comparing the marginal age groups of boys and girls, it has been observed that there are over 54 %, more common values of $W/S^2$ for girls than there are for boys.
3. In the groups of 8- and 19-year-old boys and girls, common values of $W/S^2$ are exhibited by 16.8 % and 25.6 % of the subjects respectively.
4. Values of $W/S^2$ for the boys and girls we have examined are significantly lower than the values found for the American sample population in all age groups.

KEY WORDS: Weight/Stature$^2$ — School Children — Percentile values.

Weight/stature index ($W/S^2$) is one of the best simple indicators of total body fat (TBF), particularly in girls and women aged from 6 to 50 years. It is also informative as far as 6 to 18 year old boys are concerned (Cronk, Roche 1982; Roche et al. 1981). This indicator exhibits a high correlation with percentage body fat (%BF) and TBF (total body fat) (Roche et al 1981).

The main purpose of this study is to determine:

i. changes in $W/S^2$ according to age,
ii. differences between boys and girls with regard to $W/S^2$,
iii. percentile values for the groups under investigation.

MATERIAL AND METHODS

We examined a sample of over 12,000 children from randomly selected primary and secondary schools in the Tri-City (Gdańsk, Gdynia, Sopot in the years 1985 and 1986).

Stature and body weight were measured in accordance with standard methods by means of a sliding-weight scale with a height gauge. The measurements of stature and weight were exact to 0.5 cm and 0.1 kg respectively. The data we obtained were used in calculating the indicator according to the formula $W/S^2 \times 100$, where $W$ was given in kg and $S$ in cm (Tatuń 1983).

All the data were processed statistically by calculating the arithmetic mean ($\bar{x}$), the standard deviation ($SD$), the Pearson linear correlation coefficient ($r$) its significance ($p$), and the regression equation ($y$). The coefficient of variation was calculated according to the formula $V_p = SD \times 100/\bar{x}$. Student's $t$-test was used to determine statistical differences between means. The computing was done on a TXP-1000 General Electric computer manufactured in the USA in 1990.
RESULTS

W/S² in Girls

Table 1 shows stature and body weight data and W/S² for 6450 girls. The dependence of W/S² upon age is presented in Figure 1, where the data point to a systematic increase in W/S² along with the girls' increasing age. This relationship is confirmed by a relatively high Pearson linear correlation coefficient which equals rₓᵧ = 0.993. The coefficient is extremely significant at p < 0.001.

It follows from the regression equation that in the case of girls and increase in age by one year corresponds to an increase in W/S² on the average by 0.00225 kg²/m². A detailed analysis of the data points to a considerable variability of W/S². For example, its maximal value for 8-year old girls is 120% higher than its minimal value, for 10-year olds it is 155% higher, for 17-year olds 132% higher, and for 18-year olds it is 71% higher.

Figure 2 demonstrates changes in W/S² in each consecutive age group in contrast to the immediately preceding age group together with the statistical variability of the changes. In each of the eleven 1-yr intervals values of W/S² are higher than those found in the preceding interval (see also Table 1). Yearly changes in W/S² in the oldest girls are smallest and statistically insignificant (p > 0.05). The most considerable change in W/S² is observed in girls aged 13–14 years.

A comparative analysis of the frequency of occurrence of the particular values of W/S² for 8- and 19-year old girls is shown in Figure 3. What is interesting is the fact that in both 8- and 19-year old girls values of W/S² are either particularly high or particularly low, 11.1% of 8- and 19-year old girls have common values of W/S².

W/S² in Boys

The data concerning stature and body weight together with the values of W/S² for 5825 boys are shown in Table 2, and the dependence of W/S² upon age is illustrated in Figure 4. The dependence is exceptionally strong and the linear correlation coefficient is rₓᵧ = 0.998. It follows from the regression equation that in the case of boys an increase in age by one year corresponds to an increase in W/S² on the average by 0.00558 kg²/m².

Boys also show a great variability of W/S², the maximal value of W/S² in the youngest boys being 212% higher than the minimal value. Older boys exhibit a relative stability in this respect as the maximal values of W/S² exceed the minimal ones by 63.6% in 12-year old boys, by 78.8% in 15-year old boys and by 83.8% in 18-year old boys.

Figure 5 illustrates changes in W/S² in each age group in relation to the immediately preceding age group and the statistical significance of the changes. The greatest change occurs in 14- and 16-year old boys, and the smallest in 13-year old boys. In the latter case the change is the only one which does not bear any statistical significance (see also Table 2).
As far as the differences between the mean values of \( W/S \) in girls and boys are considered, we can distinguish three age brackets (Figure 7):

1. The 8–12 age bracket, where the values are higher for boys than for girls: 3.0% higher for 8-year-old boys (\( p < 0.001 \)) and 1.7% higher for 11-year-old boys (\( p < 0.05 \)).
2. The 13–15 age bracket, where the values are slightly higher for girls than for boys (\( p > 0.05 \)).
3. The 16–19 age bracket, where the values are once again higher for boys than for girls at \( p > 0.001 \): 3.0% higher for 17-year-old boys, 6.1% higher for 18-year-old boys, and 4.6% higher for 19-year-old boys.

\[ t = \text{values of Student's t-test} \]

A comparative analysis of the frequency of occurrence of the particular values of \( W/S \) for 8- to 10-year old boys is presented in Figure 6. Common values of \( W/S \), both high and low, occur in 11.7% of boys aged 8 to 11 years. This means that 88.3% of 10-year-old boys exhibit values of \( W/S \) higher than those of 8-year-old boys.

While comparing the values of \( W/S \) for boys and girls, it should be emphasized that there is a strong dependence of those values upon age in both sexes and that the dependence is stronger in boys than it is in girls.

By analyzing the coefficients of variation (Tables 1, 2), it is possible to state that increasing age, in both boys and girls, is paralleled by a greater stability of \( W/S \) though girls display greater liability in this respect.

Although the dynamics of changes with regard to \( W/S \) is different in boys and in girls, the fact that \( W/S \) always increases in each age group in comparison to the immediately preceding age group pertains to both sexes (Tables 1, 2, Figures 2, 5).

50

51
The frequency of occurrence of the particular values of $W/S^2$ for 8- and 10-year olds of both sexes are presented in Figure 8 and Figure 9 respectively. It follows from the data that common values of $W/S^2$ are exhibited by 83.2 % of 8-year olds and by 74.4% of 10-year olds. This means that 16.8 % of 8-year old boys and 25.0 % of 10-year old boys exhibit higher values of $W/S^2$ than girls at the same age.

Percentile values of $W/S^2$ for boys and girls are given in Tables 3 and 4, and their graphic representation is shown in Figures 10 and 11.

In the channel of the 10th to 90th percentile the smallest differences in $W/S^2$ are exhibited by 9-year old girls, and the biggest differences are exhibited by 14-and 15-year old girls. As far as boys are concerned, the smallest differences in 10-year olds and the biggest ones occur in 15-year olds. In the group of 13-to 15-year old girls the mean values of $W/S^2$ expressed by medians are higher than those in the group of boys at the same age. In the other age groups the medians are higher for boys than for girls.

Table 5 shows the values of the 50th percentile of $W/S^2$ for the groups under examination together with the corresponding values for white American boys and girls (Cronk, Roche 1982). Since the 15-20 age bracket is a standard age bracket used in the American study, we have combined 18-and 19-year old subjects into one age bracket giving the mean values of their $W/S^2$.

Values of $W/S^2$ for the boys and girls we have examined are significantly lower than the values found for the American sample population in all age groups, especially in the case of girls. We can state that the biggest difference concerns 11-year old girls (values higher by 6.4 %) and 18-year old boys (values higher by 8.0 %), having assumed the relative nature of our comparison in the latter case.

CONCLUSION

1. The relationship between $W/S^2$ and age is statistically significant in the case of boys as well as girls.
2. The diversification of $W/S^2$ values in the particular groups proves that there is significant changeability in adiposity and body structure, especially in girls and younger boys.
3. By comparing the extreme age groups of boys and girls, it has been observed that there are over 54 % more common values of $W/S^2$ for girls than there are for boys.
4. In the groups of 8- and 19-year old boys and girls, common values of $W/S^2$ are exhibited by 16.8 % and 25.0 % of the subjects respectively.
